PREFACE

The research described here was performed for the National Aeronautics and Space Administration, and deals with the APOLLO Mission Reliability Assessment Study. In this Memorandum, the author uses Bayesian analysis to specify parameters of a prior distribution for two cases: (1) reliability of a unit that either performs satisfactorily throughout a mission or does not, and (2) failure rate of a unit that fails according to the exponential distribution. Prediction of demand for spares is considered in each case. The cases can be read independently.

An estimate of reliability is the posterior mean. Alternatively, the posterior distribution can be used to obtain a (subjective) confidence interval for reliability. The posterior distribution is also useful in a decision-theoretic approach to resource allocation for maximal system reliability; such a study is planned as a sequel to the present work.

This Memorandum should be of interest to those working on reliability estimation; allocation of investment among system components to achieve maximum system reliability; and stockage applications.

SUMMARY

This Memorandum specifies the parameters of a prior distribution for two cases: the reliability of a unit that either performs satisfactorily throughout a mission or does not; and the failure rate of a unit that fails according to the exponential distribution.

Bayesian analysis is an obvious approach in estimating reliability parameters from mixed data sources such as: (1) test results; (2) information on analogous components; and (3) engineering estimates. The prior distribution, of necessity subjective, is (ideally) based on (2) and (3) alone. Test results are then merged with the prior via Bayes' rule to obtain a posterior distribution. Roughly, the spread of the prior distribution is inversely proportional to the degree of prior belief, and determines how heavily it will be weighted when combining it with test data.

A topic that most writers on Bayesian analysis avoid is how to specify the parameters of the prior distribution based on (2) and (3). We give a method for specifying these parameters that requires only information corresponding (i) to the most likely value of reliability and (ii) to the subjective odds that the error in this estimate is less than a given percent. We have computed tables of parameters of the prior distribution corresponding to these subjective inputs. These appear in the Appendix.

As an application of Bayesian analysis, we consider prediction of demand for spares in both the GO NO-GO and constant failure rate cases.

1. SPECIFYING THE PARAMETERS OF A PRIOR DISTRIBUTION FOR RELIABILITY OF A GO NO-GO UNIT

Suppose we have a unit that works with probability p but that the precise value of p is unknown. If we were totally ignorant about the value of p, then our prior belief would be reflected by a uniform distribution over [0,1]. However, intuition tells us that total ignorance is an anomaly; that is, our prior distribution is really not flat. A smooth, unimodal prior distribution having support (0,1) with peak over what we believe to be the most likely value of p seems appropriate. In addition, the beta distribution is a natural conjugate [5] prior distribution; i.e., the posterior distribution is again a beta distribution (with parameters transformed according to Bayes' rule). The beta density with positive parameters (a,b) is given by

(1.1)
$$\beta(p|a,b) = \begin{cases} c p^{a-1}(1-p)^{b-1}, & 0$$

with c as a normalizing factor. The mean and variance are, respectively:

(1.2)
$$\mu = a/(a+b),$$

(1.3)
$$\sigma^2 = ab/[(a+b)^2(a+b+1)],$$

and, for a, b > 1, there is a unique mode at

(1.4)
$$\theta = (a-1)/(a+b-2).$$

After observing test data, say a sample with m successes and n failures, the posterior density is $\beta(p \mid a+m, b+n)$ from the Bayes' rule relation: posterior density = prior density x likelihood function x a normalizing factor independent of p. As more test data are observed, the posterior distribution is updated. (The updating procedure is valid

only if all units are stochastically identical. If, for example, design changes are made, as a result of failure mode analysis, a new prior distribution should be constructed from scratch).

It remains to specify the parameters (a,b). The procedure we give is heuristic and, while not the simplest mathematically, uses information that corresponds to subjective notions. * For example. one is less likely to have a feel for the variance of the prior distribution than for the error in his estimate of the most likely value of p. Of course, if we were interested in psychological consistency, we could ask for an estimate of the variance as well -but we shall ignore such considerations here. If the designer/ engineer being asked these questions has seen any test data, it is probably impossible for him to ignore them. Therefore, in this case, it is suggested that the prior distribution be based on all information the designer knows. On the other hand, if the designer has not seen any test data, this is all to the good; test results are then accounted for in the posterior distribution. Whenever possible, the parameters of the prior distribution should be specified before any tests are performed.

Suppose that our subjective assessment of the most likely value ** of p is \hat{p} ; then we set

(1.5)
$$(\hat{a}-1)/(a+\hat{b}-2) = \hat{p}.$$

$$\hat{a} = \hat{\sigma}^{-2} \hat{\mu}^{2} (1 - \hat{\mu}) - \hat{\mu}$$

$$\hat{b} = \hat{\sigma}^{-2} \hat{\mu} (1 - \hat{\mu})^{2} - (1 - \hat{\mu}).$$

For example, if $\hat{\mu}$ and $\hat{\sigma}$ were subjective estimates of the mean and variance, respectively, of the prior distribution, then solving the equations (1.2) and (1.3) yields

The analysis of the case where one estimates the mean rather than the mode is analogous. We give no details for the former case, except that numerical results for both cases are given in Tables 1 and 2 in the Appendix.

Next, we ask what odds we would give that the true value of p lie's in $(\hat{p}-k\hat{p}, \hat{p}+k\hat{p})$, where 0 < k < 1. For example, if k = .1, then we ask what the chance is that the error in our estimate is less than 10 percent. Suppose that the subjective odds are x to y; then, setting v = x/(x+y), we have

(1.6)
$$\int_{\hat{p}-k\hat{p}}^{\hat{p}+k\hat{p}} g(p|\hat{a},\hat{b}) dp = v.$$

Thus, to find \hat{a} and \hat{b} , it suffices to specify \hat{p} , k, and v. If the views of several people are solicited, it is suggested that the decision-maker take weighted averages, the weights $\{\alpha_i\}$ depending on the technical backgrounds and personalities of the people involved. Some may be conservative in their estimates, while others are optimistic. It is suggested that in asking the questions the decision-maker fix the value of v. If person i responds (\hat{p}_i, k_i) , then $\hat{p} = \sum \alpha_i \hat{p}_i / \sum \alpha_j$ and $k = \sum \alpha_i k_i / \sum \alpha_j$.

Equations (1.5) and (1.6) can be resolved by using the tables of the incomplete beta function [3], but to expedite matters we have provided a table of (\hat{a}, \hat{b}) in the Appendix corresponding to selected values of (u,v,k), where $u = \hat{p}$.

Defining

(1.7)
$$\phi(t;u,v,k) = v - \frac{\int_{u(1-k)}^{\min(1,u(1+k))} \frac{u(t-1)}{p^{1-u}} (1-p)^{t-1} dp}{\int_{0}^{1} \frac{u(t-1)}{p^{1-u}} (1-p)^{t-1} dp}$$

and

(1.8)
$$\phi[g(u,v,k);u,v,k] = 0$$
,

it follows from (1.5) and (1.6) that

(1.9)
$$\hat{b} = g(\hat{p}, v, k),$$

(1.10)
$$\hat{a} = [\hat{p}(\hat{b}-2) + 1]/(1-\hat{p}).$$

A uniform prior is suggested, if there is not enough prior information to quantify sensibly; however, it is felt that introspection will generally reveal the contrary.

In base stockage application [2], appropriate levels of spares inventory must be determined. To provision spares properly, an estimate of the demand distribution is required. For this, the Poisson approximation may be useful. Assuming that p is near one and the sample size n (say, aircraft landings or space vehicle launchings) is large, the probability of k failures, corresponding to demands for spares of a given type, is closely approximated by

(1.11)
$$f(k|p,n) = \lceil n(1-p) \rceil^{k} e^{-n(1-p)}/k!.$$

Removing the conditioning on p, the demand distribution is

(1.12)
$$g(k|a,b,n) = \int_0^1 f(k|p,n) \beta(p|a,b) dp.$$

An approximation to g(k|a,b,n) is obtained by using the mean of the prior distribution [a/(a+b)] in place of p in (1.11). We do not know how good this approximation is.

^{*}We assume that the failure distribution over successive missions is geometric (i.e., no memory). The part in question is assumed stressed (used) exactly once per mission -- or, with obvious modifications, twice per mission. If it is stressed continuously, the results of Sec. 2 can be applied; of course, if all missions have the same length, we get a reduction back to the case considered here.

If the distribution of n, say $\phi(n)$, is known, then the distribution of the number of failures is

(1.13)
$$h(k|a,b) = \sum_{n} g(k|a,b,n) \phi(n).$$

To the author this indirect route to demand prediction seems preferable to a direct attack because the former is more physically motivated.

A device sometimes used is to inflate the estimate of demand deliberately in order to cause a larger provisioning of buffer stocks, with the object of reducing the incidence of stockouts due to demand fluctuation. The author feels that the approach outlined in the next paragraph is more rational.

With an unbiased estimate of demand, the proper inventory level can be determined by a decision-theoretic approach. Let L(k,s) be the loss when k units are demanded and s units are stocked. The minimal expected loss L^O is

(1.14)
$$L^{0} = \min \sum_{k=0}^{\infty} L(k,s) h(k|a,b).$$

Minimizing $L(\bar{k},s)$, where \bar{k} is the estimate of mean demand, may be grossly incorrect.

$$L(k,s) = c_1 s + c_2 \max(0,s-k) + c_3 \max(0,k-s),$$

where c_1 is the unit purchase cost, c_2 is the unit holding cost, and c_3 is the unit stockout cost.

^{*}Predicting n via a Bayesian approach -- perhaps in conjunction with spectral analysis of time series -- may be appropriate. This involves simply one more conditioning-unconditioning in (1.13). Since the values of n over successive time periods may be autocorrelated, spectral analysis may be useful in finding a suitable parametric form for the distribution of n. For a treatment of spectral analysis, see Yaglom [6].

^{**} For example,

2. SPECIFYING THE PARAMETERS OF A PRIOR DISTRIBUTION FOR FAILURE RATE

Suppose that a unit has constant failure rate θ , fixed but unknown. We assume a (natural conjugate [5]) prior distribution with density of the form

(2.1)
$$g(\theta|a,b) = a^b \theta^{b-1} e^{-a\theta}/\Gamma(b)$$
,

where the parameters (a,b) are to be specified. Its mean and variance are:

(2.2)
$$\mu = b/a$$
,

$$\sigma^2 = b/a^2,$$

respectively. There is a unique mode at (b-1)/a, $b \ge 1$, but it is felt that the mean time to failure is more amenable to subjective assessment in this case.

If the subjective estimate of the mean time to failure is \hat{v} , then using (2.2) we set

(2.4)
$$\hat{b}/\hat{a} = 1/\hat{v}$$
.

Based on subjective odds, let v be the chance that the failure rate exceeds k/\hat{v} . This yields

(2.5)
$$\int_{k/\hat{v}}^{\infty} g(\theta | \hat{a}, \hat{b}) d\theta = v.$$

Equations (2.4) and (2.5) could be resolved by using tables of the incomplete gamma function [4], but this would be a tedious job. * To save time, for selected values of k and v, Table 3 of the Appendix provides the corresponding \hat{h} , where

$$\hat{a} = \hat{h}_{\nu},$$

$$\hat{b} = \hat{h}.$$

Defining

(2.8)**
$$\delta(h;k,v) = v - \int_{k}^{\infty} g(\theta|h,h) d\theta,$$

(2.9)
$$\delta[\rho(k,v);k,v] = 0$$
,

we see that

$$\hat{a} = 1/\hat{v}\hat{\sigma}^2$$

$$\hat{b} = 1/(\hat{v}\hat{\sigma})^2.$$

However, it is felt that intuition for σ^2 would be poor. ** Note that

$$\int_{k}^{\infty} g(\theta|h,h) d\theta = \Gamma(h,hk)/\Gamma(h,0),$$

where

$$\Gamma(a,x) = \int_{x}^{\infty} e^{-u} u^{a-1} du.$$

A standard subroutine for computing $\Gamma(a,x)$ is available.

^{*}If we had used a subjective estimate, say $\hat{\sigma}^2$, of the variance of the prior distribution instead of (2.5), then using (2.3) and (2.4) we would have the explicit expressions

(2.10)
$$\hat{h} = \rho(k,v)$$
.

In specifying the parameters of the prior distribution, we refer to the suggestions given in Sec. 1 for handling data already on hand. Failure data (except that used in forming the prior distribution) are incorporated in the posterior distribution by Bayes' rule. Having observed failures at ages t_1, \ldots, t_k , and a nonfailed group with ages t_{k+1}, \ldots, t_m , the posterior density is

$$g(\theta | a + \sum_{i=1}^{m} t_i, b+k).$$

This gives us our current prior distribution, which is updated as more observations are recorded. If, for example, the unit corresponding to t_j , j > k, fails at t', updating yields

$$g(\theta | a + \sum_{i=1}^{m} t_i + (t'-t_j), b+k+1).$$

We now give an application to demand prediction. Suppose each of n units operates continuously until failure, at which time it is replaced instantaneously (for practical purposes) by a unit as good as new. These failures generate the demands for spares and/or repair. If each unit has constant failure rate θ , the probability of k demands in time T is $p(k \mid n\theta T)$, where

(2.11)
$$p(k|\lambda) = \lambda^{k} e^{-\lambda k}/k!;$$

^{*}If the failure distribution were $1-e^{-\theta x^{\alpha}}$ (Weibull with known shape parameter α), replace t_i by t_i^{α} , $i=1,\ldots,m$.

that is, demand is Poisson with rate $n\theta$. Removing the conditioning on θ , the probability of k demands is

(2.12)
$$f(k|a,b,n,T) = \int_0^\infty p(k|n\theta T) g(\theta|a,b) d\theta.$$

If n and/or T is a random variable, we can further uncondition in a similar manner.

REMARKS. If, in fact, the life distribution of the jth unit has mean μ_i and is nonlattice but not necessarily exponential, then [1], with

$$\theta = (1/n) \sum_{j=1}^{n} \mu_{j}^{-1} \text{ and } n \to \infty,$$

the stationary demand distribution becomes $p(k \mid n\theta T)$. If planned replacement takes place at age τ , the same result holds if we replace μ_j by the mean of the distribution truncated at τ . (In a more sophisticated replacement policy, the planned replacement age should ideally depend on the current inventory level.) If replacement can take a significant amount of time (due, for example, to stockouts or nonnegligible repair times), then the replacement time distribution should be convolved with the failure distribution, and the mean of the resulting distribution used in place of μ_j .

For aircraft spares provisioning, a somewhat different model of the demand process may be appropriate. Suppose that a part, used only when the aircraft is flying, has constant failure rate θ during flight and failure rate 0 on the ground. Let flights to the base originate from points $\{1, \ldots, m\}$, with respective flying times $\{w_1, \ldots, w_m\}$.

^{*}See Sec. 1 for the case where the unit is not stressed continuously during flight.

During a period of length T, let \mathbf{n}_i be the number of flights to the base from point i. The probability of k demands during time T is

(2.13)
$$D(k|T) = \sum_{(k_1, \dots, k_m) \in S_k} {n_i \choose k_i} v_i^{k_i} (1-v_i)^{n_i-k_i},$$

where

(2.14)
$$v_i = 1 - e^{-\theta w_i}$$
,

(2.15)
$$S_{k} = \left\{ (k_{1}, \dots, k_{m}) : \sum_{i=1}^{m} k_{i} = k \right\}.$$

If all the $\mathbf{v_i}$'s are near 0 and all the $\mathbf{n_i}$'s are large, then we have the Poisson approximation

(2.16)
$$D(k|T) \approx p \left(k | \sum_{i=1}^{m} n_i v_i \right) .$$

When the n_1 's and θ are unknown, we condition and then uncondition in the usual way. If θ has a prior distribution $g(\theta | a, b)$ given by (2.1), then

$$(2.17) p\left(k \mid \sum_{i=1}^{m} n_i v_i; a, b\right) = p\left(k \mid \sum_{i=1}^{m} n_i \left[1 - \left(\frac{a}{a + w_i}\right)^b\right]\right).$$

APPENDIX

In this Appendix we give tables of parameters of prior distributions corresponding to subjective assessments of reliability, as described in Secs. 1 and 2. The entries in the tables were computed using a program written by Mrs. Sarah Higgins, with the assistance of Robert Mobley and the author. Several test cases were computed by hand (using tables) for each program, with agreement to more than four significant figures throughout. The programs are believed to be completely debugged and are listed here for the convenience of those who may want values that are not tabulated. Tables 1 and 2 refer to Sec. 1 (beta prior). Table 3 refers to Sec. 2 (gamma prior). Asterisks in the tables indicate that the rootfinder did not locate a root within the allotted time.

August 1966 RB-5084

RM-5084-NASA, A Bayesian Approach to Reliability Assessment, B. L. Fox, RAND Memorandum, August 1966, 30 pp.

<u>PURPOSE</u>: To specify the parameters of a prior distribution for two cases: the reliability of a unit that either performs satisfactorily throughout a mission or does not, and the failure rate of a unit that fails according to the exponential distribution. Prediction of demand for spares is considered in each case.

SCOPE: Bayesian analysis is an obvious approach to estimating reliability parameters from such mixed data sources as test results, information on analogous components, and engineering estimates. The prior distribution, of necessity subjective, is ideally based solely on the latter two sources. This study gives a method for specifying the parameters of the prior distribution, requiring only information corresponding to the most likely value of reliability, and to the subjective odds that the error in this estimate is less than a given percentage. Testing data are then merged with the prior distribution via Bayes rule to obtain a posterior distribution. Roughly speaking, the spread of the prior distribution is inversely proportional to the degree of prior belief and determines how heavily the distribution will be weighted when it is combined with test data. Tables of the parameters of the prior distribution, computed according to the method described, appear in the Appendix.

BACKGROUND: This research was done by RAND for the National Aeronautics and Space Administration in connection with the Apollo mission reliability assessment study. It should be of interest to those working on reliability estimation, allocation of investment among system components to achieve maximum system reliability, and stockage applications.
